3 **ABSTRACT:** Codenitrification is a reactive nitrogen (N) removal pathway producing hybrid dinitrogen ( $N_2$ ) by combining nitrite  
 4 ( $NO_2^-$ ) and a partner-N substrate. Abiotic codenitrification also produces hybrid  $N_2$  through nitrosation of organic N by  $NO_2^-$ , but  
 5 it is poorly constrained in soil N cycles. We determined the importance of abiotic codenitrification in soils and examined factors  
 6 controlling abiotic codenitrification using live soils, sterile soils, and sterile solutions. Abiotic codenitrification in sterile soils ranged  
 7 from  $0.12 \pm 0.001$  to  $0.60 \pm 0.08$  nmoles  $^{29}N_2-N$   $g^{-1} day^{-1}$ , which accounts for 2.3 to 8.2% of total  $N_2$  production measured in live  
 8 soils. Increased abiotic  $N_2$  production was observed in soils with the addition of an organic N partner (glutamine). Consistent with  
 9 previous work, higher rates were observed in lower-pH soils, but the highest rate was found in the soil with the highest  
 10 carbon:nitrogen (C:N) ratio. We further investigated a range of organic N partners and the influence of concentration and pH on  
 11 abiotic codenitrification in solution. Similar to sterile soil incubations, abiotic  $^{29}N_2$  production was negatively correlated with  
 12 increasing pH in solution. Greater rates of abiotic  $^{29}N_2$  production were measured as the substrate concentration increased and pH  
 13 decreased. Solution experiments also showed that addition of organic N partners increased abiotic codenitrification rates, which are  
 14 positively correlated with the C:N ratios of organic N partners. This is the first study demonstrating the importance of N removal  
 15 through abiotic codenitrification in acidic soils and the C:N ratio of organic N partners as a controlling factor in abiotic  
 16 codenitrification.

1 **1. INTRODUCTION**

18 Excess nitrogen (N) in the environment has widespread effects  
 19 on ecosystems, biodiversity, human health, and climate, yet  
 20 pragmatic solutions for removing excess N remain elusive.<sup>1</sup>  
 21 The different oxidation states of N facilitate its participation in  
 22 a variety of enzymatically and chemically mediated reactions,  
 23 thus making the N cycle extremely complex. N removal  
 24 pathways, which we define here as transformations of reactive  
 25 N to inert dinitrogen ( $N_2$ ) gas, are important components of  
 26 the N cycle in soils and waterways.<sup>2</sup> Current N cycle paradigms  
 27 focus on enzymatically mediated N removal processes such as  
 28 denitrification, codenitrification, and anammox. These micro-  
 29 bial processes can transform reactive forms of N, such as  
 30 ammonium ( $NH_4^+$ ), nitrite ( $NO_2^-$ ), or nitrate ( $NO_3^-$ ), to  
 31 inert  $N_2$  gas. Analogous to these biotic processes are abiotic  
 32 reactions that also produce  $N_2$ , including chemodenitrification  
 33 and abiotic codenitrification. Chemodenitrification couples the

34 reduction of  $NO_2^-$  to the oxidation of metals, thus forming the  
 35 greenhouse gas nitrous oxide ( $N_2O$ )<sup>3–5</sup> or inert  $N_2$  from a  
 36 single N source.<sup>6</sup> Abiotic production of hybrid  $N_2$ , referred to  
 37 here as abiotic codenitrification, occurs through nitrosation of  
 38 organic nitrogenous molecules (organic Ns) by  $NO_2^-$ , thus  
 39 forming  $N_2$  from two independent N sources.<sup>7</sup> The  
 40 contribution of abiotic codenitrification to N removal and  
 41 release of  $N_2$  gas is relatively unknown in both terrestrial and  
 42 aquatic ecosystems.

$\text{NO}_2^-$  is the well-known precursor or 'gateway' to biotic denitrification, anammox, and codenitrification processes;<sup>8</sup> this is also true for abiotic codenitrification and chemodenitrification.<sup>3,7</sup> Abiotic codenitrification is more likely to occur in acidic environments, where nitrous acid ( $\text{HNO}_2^-$ ) is in equilibrium with NO and nitric acid ( $\text{HNO}_3$ ).<sup>9</sup> Ions of NO, such as nitrosonium ( $\text{NO}^+$ ),<sup>10</sup> are strong nitrosation agents.<sup>11,12</sup> The oxidized form of nitric oxide ( $\text{NO}^+$ ) is a key species in N-nitrosation reactions, where the  $\text{NO}^+$  is transferred to a nucleophilic aryl or alkyl amine that is then deprotonated and dehydrated.<sup>7,10</sup> The incorporation of  $\text{NO}^+$  into the organic molecule may then form an unstable intermediate diazonium ion, which disassociates to a positively charged organic molecule ( $\text{R}^+$ ) and  $\text{N}_2$ .<sup>13</sup> Some fraction of the immobilized N remains in organic N, and some fraction is released as hybrid  $\text{N}_2$ .<sup>11</sup> Controls on the production of abiotically formed  $\text{N}_2$  are not clearly defined, but may be linked to pH, substrate concentration, or the specific nucleophile, which we refer to here as the organic N partner.<sup>14</sup>

While abiotic  $\text{N}_2$  production is fundamentally controlled by pH,<sup>15</sup> it has also been shown to increase with  $\text{NO}_2^-$  concentration<sup>6</sup> and organic N concentration.<sup>14,16</sup> Lim et al. (2018) reported that abiotic  $\text{NO}_2^-$  decomposition accounted for 10–20% of the  $\text{NO}_2^-$ -N conversion to nitroso-compounds in acidic soils. Nelson and Bremner (1969) reported higher  $\text{N}_2$  production and  $\text{NO}_2^-$  decomposition for acidic soils, as compared to neutral soils. These studies point out the importance of pH in abiotic codenitrification. However, it is difficult to tease out a single factor contributing to abiotic  $\text{N}_2$  production in complex soil matrices. While the abiotic decomposition of  $\text{NO}_2^-$  at low pH is clear, other factors, such as the presence of metals, substrate concentration, or organic N partners, may also influence observed abiotic  $\text{N}_2$  production.<sup>17,18</sup>

A review of  $\text{NO}_2^-$  accumulation in soils indicated that up to 40% of added  $\text{NO}_2^-$  may react abiotically with organic compounds,<sup>19</sup> resulting in release of gaseous N,<sup>11,13,14,20</sup> but it remains unclear what is driving abiotic conversion of reactive N to inert  $\text{N}_2$ . This abiotic reaction requires an organic, nitrogenous partner, which raises questions about the extent to which these partner-N compounds control rates of abiotic codenitrification. Defining the factors controlling abiotic codenitrification is imperative to determining (a) the environmental relevance of this process, (b) implications for reported reactive N removal data, and (c) how to assess abiotic processes in the complex N cycle.

The objectives of this study were to examine the factors controlling abiotic codenitrification and its importance in soil N removal by comparing it to biotic  $\text{N}_2$  production mediated by anammox, codenitrification, and denitrification. We investigated if abiotic codenitrification is stimulated by the addition of an organic partner-N (glutamine) for a wide range of sterile soils—from a New Zealand volcanic to a North Dakota, US silty loess<sup>21,22</sup> and compared abiotic  $\text{N}_2$  and  $\text{N}_2\text{O}$  production. We also conducted sterile solution experiments with different pH conditions,  $\text{NO}_2^-$  concentrations, and partner-N substrates to identify the chemical factors controlling abiotic codenitrification.

## 2. MATERIALS AND METHODS

**2.1. Soil Sample Collection and Sterilization.** Soil samples were collected from five grassland research sites located in New Zealand (NZ) and the United States (U.S.).

The three NZ grassland sites described by van der Weerden (2016) represent the Waikato (NZ6 Volcanic), Manawatu (NZ5 Fluvial), and Canterbury (NZ1 Stony) regions. One U.S. grassland site is located in the Northern Great Plains in the state of North Dakota (US2 Silty Loess), and the other is located in the southeastern U.S. Coastal Plains region in the state of North Carolina (US3 Clayey).<sup>22</sup> During the spring of 2018, four sample points were randomly selected at each site within a 10 m × 10 m plot. Within each plot, two small soil cores (3 cm diameter × 10 cm depth) were collected and composited to form one sample. A separate larger soil core (7 cm diameter × 10 cm depth) was collected in each plot to determine bulk density. Each of the five composite soil samples was sieved (2.0-mm) and separated into two parts: one was stored at 4 °C for soil measurement of physiochemical properties, and the other was sterilized for use in incubation experiments. Sterilization was performed by applying a dose of 27.8 kGy (60Co)  $\gamma$ -irradiation (Sterigenics, Haw River facility, North Carolina, US). The  $\gamma$ -irradiated soil was stored for approximately 1 month at 4 °C before use. Gamma irradiation was chosen because this method is reportedly highly effective at killing microorganisms in soil and applicable to this type of research.<sup>12</sup> Furthermore,  $\gamma$ -irradiation imposes less severe effects on relevant physical and chemical properties, as compared to autoclaving, which is known to induce quite profound changes in both the structure and chemistry.<sup>23</sup> Sterility of  $\gamma$ -irradiated soil was assessed in the laboratory by incubating 1 g of  $\gamma$ -irradiated soil representing each site in nutrient broth media (BD Difco™) for comparison with a live soil control from the same site. Sample turbidity was monitored daily for 1 week with a Milton Roy Spectronic 401 (Spectronic Instruments Rochester, NY). Turbidity remained unchanged for all  $\gamma$ -irradiated samples, but live controls (unirradiated soil) did show growth.

In addition to testing for sterility, we measured extractable mineral N, soil pH, total organic carbon (TOC), and total nitrogen (TN). Mineral N extraction was performed by amending soil samples with 2 M KCl and then shaking for 1 h prior to filtration with a Whatman 0.45  $\mu\text{m}$  pore size filter (GE Healthcare Life Sciences). Extracts were analyzed for nitrate ( $\text{NO}_3^-$ ), nitrite ( $\text{NO}_2^-$ ), and ammonium ( $\text{NH}_4^+$ ) with a Lachat QuikChem 8000 automated ion analyzer (Lachat Instruments, Milwaukee, WI, USA). Soil pH was measured using a Corning pH/ion meter 450 with an Accumet probe using a 1:2 ratio of air-dried soil to deionized water mixture. Soil TOC and TN were measured using a CHN 4010 Elemental Combustion System on air-dried soil (Costech Analytical, Valencia, CA, USA).

**2.2. Measurement of Abiotic Codenitrification in Soils.** Approximately 1 g of sterilized soil was placed in a 12 ml exetainer tube amended with one of the following solutions (1 mL volume): (a) 100 nmoles N as  $\text{Na}^{15}\text{NO}_2$  (Cambridge Isotope, 98%atm) only, (b) 100 nmoles N as  $\text{Na}^{15}\text{NO}_2$  and 100 nmoles glutamine, or (c) 100 nmoles glutamine. In previous studies, abiotic codenitrification was performed using a robotized gas chromatography system, which required high levels of  $\text{NO}_2^-$  (>250  $\mu\text{moles}$ ) to overcome detection limit constraints.<sup>24</sup> However, high concentrations of soil  $\text{NO}_2^-$  tend to be rare or transient in nature. Here, we used concentrations more closely aligned with natural occurrence. Concentrations of  $\text{NO}_2^-$  in unfertilized soil typically vary from 0.01 to 4  $\mu\text{moles}$  per g soil,<sup>19</sup> and fertilizers tend to cause elevated accumulations of  $\text{NO}_2^-$ , such as anhydrous ammonia<sup>25,26</sup> and

167 urea.<sup>27,28</sup> The isotopic composition of <sup>29,30</sup>N<sub>2</sub> was measured by  
168 isotope ratio mass spectrometry (IRMS) on a gas bench  
169 isotope ratio mass spectrometer (Delta V Plus, Thermo Fisher  
170 Scientific, Waltham, MA) that could reliably detect nanomolar  
171 changes in <sup>29,30</sup>N<sub>2</sub>. The unlabeled glutamine-only vials served  
172 as a background N<sub>2</sub> control. The amounts of <sup>29,30</sup>N<sub>2</sub> produced  
173 were calculated using the method described by Song and  
174 Tobias.<sup>29</sup> Gas-tight vials were prepared for each N amendment  
175 (3 reps), sample collection site (S), and time point (2), for a  
176 total of 90 samples, plus calibration checks. After flushing the  
177 headspace of the exetainer tubes with helium (He) gas for 5  
178 min, the first time point (T<sub>0</sub>) was immediately analyzed using  
179 IRMS, and the remaining samples were incubated in the dark  
180 for 24 h. The 24 h-incubated samples (T<sub>final</sub>) were analyzed  
181 by IRMS to measure rates of <sup>29,30</sup>N<sub>2</sub> production. Similar  
182 incubation and measurement protocols were performed for the  
183 buffer solution experiments described below.

184 Live soil incubation experiments were conducted with the  
185 NZ soils (NZ1, NZ5, and NZ6) to measure the rates of biotic  
186 N<sub>2</sub> production. Approximately 1 g of soil was placed in a 12 mL  
187 exetainer tube amended with 100 nmoles N as Na<sup>15</sup>NO<sub>3</sub><sup>-</sup>  
188 (Cambridge Isotope, 99%atm). Nitrate (NO<sub>3</sub><sup>-</sup>) was used to  
189 measure total N<sub>2</sub> production mediated by abiotic and biotic  
190 pathways in soil samples similar to the methods described by  
191 Lim et al. (2018). Gas-tight vials were prepared for each  
192 sample collection site (3) and time point (2) in duplicate, for a  
193 total of 12 samples, plus calibration checks. The exetainer  
194 tubes were flushed with He gas for 5 min and preincubated for  
195 24 h at room temperature. The preincubated tubes were  
196 flushed again for 5 min with He gas and then amended with  
197 0.1 mL of <sup>15</sup>N-NO<sub>3</sub><sup>-</sup> (1 mM and 99%atm). The initial time  
198 point samples (T<sub>0</sub>) were treated with 50% zinc chloride  
199 (ZnCl) immediately following <sup>15</sup>NO<sub>3</sub><sup>-</sup> addition to terminate  
200 biotic N<sub>2</sub> production. Remaining samples were incubated for 1  
201 h (T<sub>1</sub>) and then treated with 50% ZnCl. The production of  
202 <sup>29,30</sup>N<sub>2</sub> from live soil incubations was measured using IRMS,  
203 and rate calculations were conducted as described by Song and  
204 Tobias.<sup>29</sup> Extractable NO<sub>2</sub><sup>-</sup> and NO<sub>3</sub><sup>-</sup> of live soils were  
205 measured as described above and used to calculate the diluted  
206 <sup>15</sup>N ratio (atm %) in each soil incubation experiment.

207 **2.3. Measurements of Abiotic Codenitrification in**  
208 **Buffer Solution under Varying Conditions of pH and N**  
209 **Substrates.** Phosphate buffer (0.1 M K<sub>2</sub>HPO<sub>4</sub> and 0.1 M  
210 KH<sub>2</sub>PO<sub>4</sub>) was prepared with autoclaved MilliQ water and used  
211 to determine the effects of the N substrate and pH conditions  
212 on abiotic codenitrification. To test the effects of NO<sub>2</sub><sup>-</sup>  
213 concentrations on N<sub>2</sub> production by abiotic codenitrification,  
214 the pH of the phosphate buffer was adjusted to pH 6 with a  
215 hydrochloric acid (5%) solution. This pH (6) was selected  
216 because the pH for all soil samples used in incubation was < 7  
217 (Table 2). The pH-adjusted buffer was filter-sterilized with a  
218 Whatman 0.45 μm filter. The sterilized buffer (1 mL) was  
219 pipetted into 12 mL exetainer tubes and amended with 1 mM  
220 <sup>14</sup>N-glycine, an unlabeled organic partner-N substrate. Each  
221 tube with buffer plus glycine was amended with varying  
222 concentrations of Na<sup>15</sup>NO<sub>2</sub><sup>-</sup> (0, 5, 10, 50, 100, 500, and 1000  
223 μM, Cambridge Isotope, 98% atm). Three replicates were  
224 prepared for each <sup>15</sup>NO<sub>2</sub><sup>-</sup> concentration. After flushing the  
225 headspace of the tubes with helium gas, the tubes were  
226 incubated for 24 h (T<sub>final</sub>) to measure <sup>29,30</sup>N<sub>2</sub> using IRMS.  
227 Controls with <sup>15</sup>NO<sub>2</sub><sup>-</sup> only and the partner substrate

(unlabeled glycine) only were also prepared in triplicate and  
used to determine background <sup>29,30</sup>N<sub>2</sub> after 24 h.

228  
229  
230 To test the effect of partner-N concentration (glycine) on  
231 <sup>29,30</sup>N<sub>2</sub> production, we spiked the phosphate buffer (pH 6),  
232 amended with 1 mM <sup>14</sup>NO<sub>2</sub><sup>-</sup> with varying concentrations of  
233 <sup>15</sup>N glycine (0, 1, 10, 100, and 1000 μM, Cambridge Isotope,  
234 98%atm). The effect of the specific partner-N substrate on  
235 abiotic codenitrification was further tested with different  
236 inorganic and organic Ns including ammonium (NH<sub>4</sub><sup>+</sup>), urea  
237 (Ure), alanine (Ala), arginine (Arg), glycine (Gly), glutamine  
238 (Glu), histidine (His), lysine (Lys), ornithine (Orn), and  
239 tryptophan (Trp). The partner-N substrates were selected  
240 based on their relevant presence in soils.<sup>30</sup> The phosphate  
241 buffer (pH 6) with <sup>15</sup>NO<sub>2</sub><sup>-</sup> (1 mM N) was prepared, and 1 mL  
242 of the buffer solution was aliquoted in 12 mL exetainer tubes.  
243 Different partner-N substrates (1 mM N) listed above were  
244 added to the tubes in triplicate of each N substrate. The  
245 production of <sup>29,30</sup>N<sub>2</sub> was measured after 24 h incubation with  
246 IRMS as described above.

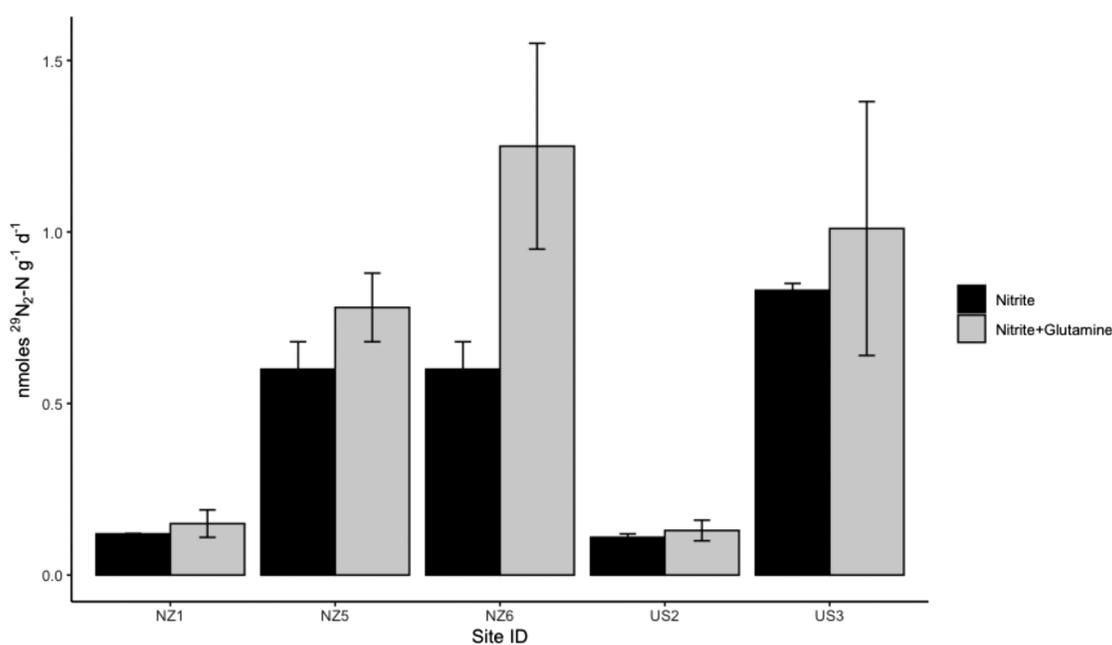

247 The effect of pH on abiotic codenitrification was tested  
248 along a pH gradient (pH 3, 4, 5, 6, 7, and 8), which covers a  
249 wide variety of environmental pH values.<sup>31</sup> The phosphate  
250 buffer was adjusted to each pH with hydrochloric acid (5%)  
251 and/or potassium hydroxide (10%). The pH-adjusted  
252 solutions (1 mL) were aliquoted into 12 mL exetainer tubes  
253 and amended with 1 mM N of both <sup>15</sup>NO<sub>2</sub><sup>-</sup> and partner <sup>14</sup>N  
254 substrates. The partner <sup>14</sup>N substrates include NH<sub>4</sub><sup>+</sup>, Ure, Gly,  
255 Glu, and Orn. After substrate amendment, triplicate reactions  
256 were incubated for 24 h prior to measurement of <sup>29,30</sup>N<sub>2</sub>  
257 production by IRMS.

#### 2.4. Comparison of Abiotic N<sub>2</sub> and N<sub>2</sub>O Production.

258  
259 To compare the abiotic production of N<sub>2</sub> and N<sub>2</sub>O, incubation  
260 experiments similar to those described above were conducted  
261 using sterile solution and soils. Phosphate buffer adjusted to  
262 pH 5 was aliquoted into gas-tight vials prepared with one of  
263 the following treatments: (a) no N amendment or (b) <sup>15</sup>N-  
264 NO<sub>2</sub><sup>-</sup> and Glu (1 mM N each). In triplicate, each treatment  
265 was prepared for both products (N<sub>2</sub> or N<sub>2</sub>O) for a total of 12  
266 samples, plus calibration checks. Samples were incubated at  
267 room temperature for 24 h prior to measurement of <sup>29,30</sup>N<sub>2</sub> by  
268 IRMS, and N<sub>2</sub>O production was measured using a gas  
269 chromatograph fitted with an electron capture detector (GC-  
270 ECD: Shimadzu). Production of <sup>29</sup>N<sub>2</sub> was detected, but N<sub>2</sub>O  
271 production was negligible for both solution treatments.

272 Sterile soils from North Carolina (NC), North Dakota  
273 (ND), and New Zealand (NZ1) were used for comparison of  
274 abiotic N<sub>2</sub> and N<sub>2</sub>O production. Gas-tight vials were prepared  
275 for each N amendment (3 reps), sample collection site (3),  
276 and product (2), for a total of 54 samples, plus calibration  
277 checks. The three N amendment treatments included: (a)  
278 Control (no amendment), (b) <sup>15</sup>NO<sub>2</sub><sup>-</sup> (1 mM N and 1 μmoles  
279 N g<sup>-1</sup>), and (c) <sup>15</sup>N-NO<sub>2</sub><sup>-</sup> and Glu (1 mM N each and 1  
280 μmoles N g<sup>-1</sup>). The concentration of 1 mM NO<sub>2</sub><sup>-</sup> was  
281 required to measure N<sub>2</sub>O production above atmospheric N<sub>2</sub>O  
282 concentrations. Soil samples were incubated for 24 h prior to  
283 analysis for <sup>29,30</sup>N<sub>2</sub> by IRMS and N<sub>2</sub>O with a GC-ECD.

284 **2.5. Statistical Analyses.** The <sup>29</sup>N<sub>2</sub> produced for sterile  
285 soils incubated for 24 h was analyzed by a two-way analysis of  
286 variance (ANOVA). We evaluated (1) if soils amended with  
287 both <sup>15</sup>NO<sub>2</sub><sup>-</sup> and Glu produce more <sup>29</sup>N<sub>2</sub> than soils amended  
288 with <sup>15</sup>NO<sub>2</sub><sup>-</sup> only and (2) how <sup>29</sup>N<sub>2</sub> production varied among  
289 the five grassland sites. The ANOVA included the fixed effect  
290 of site (NZ1, NZ5, NZ6, US2, and US3), treatment (<sup>15</sup>NO<sub>2</sub><sup>-</sup>

**Figure 1.** Abiotic codenitrification rates (nmoles <sup>29</sup>N<sub>2</sub>-N g<sup>-1</sup> day<sup>-1</sup>) in each soil sample (NZ1, NZ5, NZ6, US2, and US3) for each treatment (nitrite and nitrite + glutamine). Error bars represent one standard deviation in each direction. ANOVA results indicate statistically significant effects of treatment (*p*-value <0.01), site (*p*-value <0.001), and the interaction site × treatment (*p*-value <0.05).

**Table 1.** Comparison of Abiotic and Total N<sub>2</sub> Production Rates from Soils NZ1, NZ5, and NZ6<sup>a</sup>

sample	abiotic N <sub>2</sub> rate (nmoles <sup>29</sup> N <sub>2</sub> -N g <sup>-1</sup> d <sup>-1</sup> )	total N <sub>2</sub> rate (nmoles <sup>29</sup> N <sub>2</sub> -N g <sup>-1</sup> d <sup>-1</sup> )	% abiotic N <sub>2</sub> production	<sup>15</sup> N ratio (atm %)
NZ1	0.12 ± 0.00	15.09 ± 2.57	0.80	8.18
NZ5	0.6 ± 0.08	31.54 ± 9.81	1.90	2.87
NZ6	0.6 ± 0.08	7.44 ± 2.05	8.07	2.34

<sup>a</sup>Abiotic rate determined with sterile soil incubations amended with <sup>15</sup>NO<sub>2</sub><sup>-</sup>. Total N<sub>2</sub> production rates determined with live soil incubations amended with <sup>15</sup>NO<sub>3</sub><sup>-</sup>. Percent of abiotic N<sub>2</sub> production = (abiotic N<sub>2</sub> production / total N<sub>2</sub> production) × 100. <sup>15</sup>The N ratio is the <sup>15</sup>NO<sub>3</sub><sup>-</sup>:<sup>14</sup>NO<sub>2</sub><sup>-</sup> ratio (atm %) calculated by <sup>15</sup>NO<sub>3</sub><sup>-</sup> (0.1 μmoles N g<sup>-1</sup>) added into the live soils (1 g) divided by a sum of added <sup>15</sup>NO<sub>3</sub><sup>-</sup> and extractable NO<sub>3</sub><sup>-</sup> in the live soils (NZ1 = 1.12 μmoles N g<sup>-1</sup>, NZ5 = 3.38 μmoles N g<sup>-1</sup>, and NZ6 = 4.16 μmoles N g<sup>-1</sup>).

only vs glutamine + <sup>15</sup>NO<sub>2</sub><sup>-</sup>), and interactions. A posthoc Tukey test for multiple comparisons of means was used to indicate how <sup>29</sup>N<sub>2</sub> production varied among the five grassland soils with 95% confidence intervals.

The <sup>29</sup>N<sub>2</sub> production observed with increasing <sup>15</sup>NO<sub>2</sub><sup>-</sup> or <sup>15</sup>N-Gly concentrations in buffer solution experiments was statistically analyzed with a linear model ( $y = \alpha x + \beta$ ). Data were log-transformed to meet the model assumption of normality. Modeled and observed <sup>29</sup>N<sub>2</sub> production data were compared, and R<sup>2</sup> values were reported. The effects of partner-N substrates on abiotic codenitrification were statistically evaluated based on the <sup>29</sup>N<sub>2</sub> production as compared to the control (<sup>15</sup>NO<sub>2</sub><sup>-</sup> only) with a simple one-way ANOVA. The ANOVA was followed by posthoc analysis with a Tukey test for multiple comparisons of means with a 95% family-wise confidence level. Finally, the influence of pH on <sup>29</sup>N<sub>2</sub> production was tested for each of the tested partner-N substrates using a linear model ( $y = \alpha x + \beta$ ). Modeled and observed <sup>29</sup>N<sub>2</sub> production data for each partner-N substrate were compared and the R<sup>2</sup> value reported. Data were log-transformed to meet the model assumption of normality. Significance for all tests was determined at  $\alpha = 0.05$ .

### 3. RESULTS

**3.1. Abiotic Codenitrification in Soils.** Production of <sup>29</sup>N<sub>2</sub> was clearly measured in soil samples, while <sup>30</sup>N<sub>2</sub> production was negligible. Mean values for <sup>29</sup>N<sub>2</sub> (nmoles g<sup>-1</sup> d<sup>-1</sup>) by site for each time point (± std. dev.) are shown for <sup>15</sup>NO<sub>2</sub><sup>-</sup> only and Glu plus <sup>15</sup>NO<sub>2</sub><sup>-</sup> (Figure 1). While all soils responded positively to inclusion of the Glu, as compared to <sup>15</sup>NO<sub>2</sub><sup>-</sup> only, the magnitude of this effect varied with site (site × treatment, *p*-value <0.05). NZ6 volcanic soils had a stronger response to the inclusion of glutamine (Glu) than soils collected at other sites. Abiotic <sup>29</sup>N<sub>2</sub> production increased by 100%, as compared to <sup>15</sup>NO<sub>2</sub><sup>-</sup> only for NZ6 (Figure 1). Inclusion of Glu for the remaining four sites increased <sup>29</sup>N<sub>2</sub> production by 20–30%. The average rates of <sup>29</sup>N<sub>2</sub> production (and std. dev.) by treatment and site are shown in Table S1. Soils from sites NZ1 and US2 produced less <sup>29</sup>N<sub>2</sub> than the others (US3, NZ5, and NZ6), and these two sites were not significantly different from each other (Table S2).

Three NZ soils were used to measure and compare the rates of abiotic and total N<sub>2</sub> production. <sup>29</sup>N<sub>2</sub> was the major N<sub>2</sub> gas product while <sup>30</sup>N<sub>2</sub> production was negligible in the three live soils. Considering that the <sup>15</sup>N-NO<sub>3</sub><sup>-</sup> enrichment ratios were 2.34 to 8.18 atm%, the observed <sup>29</sup>N<sub>2</sub> production can be attributed to high amounts of residual NO<sub>3</sub><sup>-</sup> in the soils ranging from 1.12 to 4.16 μmoles g<sup>-1</sup> (Table 1). Observed

<sup>29</sup>N<sub>2</sub> production in live soils could have resulted from both abiotic and biotic pathways, including abiotic codenitrification, anammox, codenitrification, and denitrification. Total N<sub>2</sub> production rates ranged from 7.44 ± 2.05 to 31.54 ± 9.81 nmoles <sup>29</sup>N<sub>2</sub>-N g<sup>-1</sup> h<sup>-1</sup>, whereas the rates of abiotic codenitrification ranged from 0.12 ± 0.001 to 0.6 ± 0.08 <sup>29</sup>N<sub>2</sub>-N g<sup>-1</sup> h<sup>-1</sup>. (Table 1 and Figure S1). Despite abiotic rates being lower than the total N<sub>2</sub> production rates, the abiotic production accounted for 0.8 to 8.2% of the total production (Table 1).

**3.2. Comparing Abiotic N<sub>2</sub> and N<sub>2</sub>O Production in Soils.** The N<sub>2</sub> production rates were higher than N<sub>2</sub>O production rates in the soils amended with both <sup>15</sup>N-NO<sub>2</sub><sup>-</sup> or <sup>15</sup>N-NO<sub>2</sub><sup>-</sup> and Glu (Figure S2). Control soils did not show any N<sub>2</sub> or N<sub>2</sub>O production. The rates of <sup>29</sup>N<sub>2</sub>-N production in the soils amended with <sup>15</sup>N-NO<sub>2</sub><sup>-</sup> (1 μmole N) ranged from 31.47 ± 2.25 to 52.12 ± 20.11 nmoles N<sub>2</sub>-N g<sup>-1</sup> d<sup>-1</sup>, whereas N<sub>2</sub>O production rates ranged from 0.51 ± 0.10 to 4.41 ± 0.85 nmoles N<sub>2</sub>O-N g<sup>-1</sup> d<sup>-1</sup> (Figure S2). Soils amended with <sup>15</sup>N-NO<sub>2</sub><sup>-</sup> and Glu (1 μmole N each) had rates of N<sub>2</sub>-N production ranging from 61.97 ± 5.17 to 71.47 ± 5.66 nmoles N<sub>2</sub>-N g<sup>-1</sup> d<sup>-1</sup> and N<sub>2</sub>O-N production rates ranging from 1.72 ± 0.21 to 3.99 ± 0.21 nmoles N<sub>2</sub>O-N g<sup>-1</sup> d<sup>-1</sup> (Figure S2). The rates of N<sub>2</sub> production were higher in all the soils amended with <sup>15</sup>N-NO<sub>2</sub><sup>-</sup> plus Glu than <sup>15</sup>NO<sub>2</sub><sup>-</sup> only. The N<sub>2</sub>O production rates in NC and NZ soils showed no difference between substrate conditions as compared to the ND soil, which had higher N<sub>2</sub>O production with <sup>15</sup>NO<sub>2</sub><sup>-</sup> and Glu addition. Overall, the abiotic N<sub>2</sub>O production in soil incubation was only 1–12% of the N<sub>2</sub> production by abiotic codenitrification in soils.

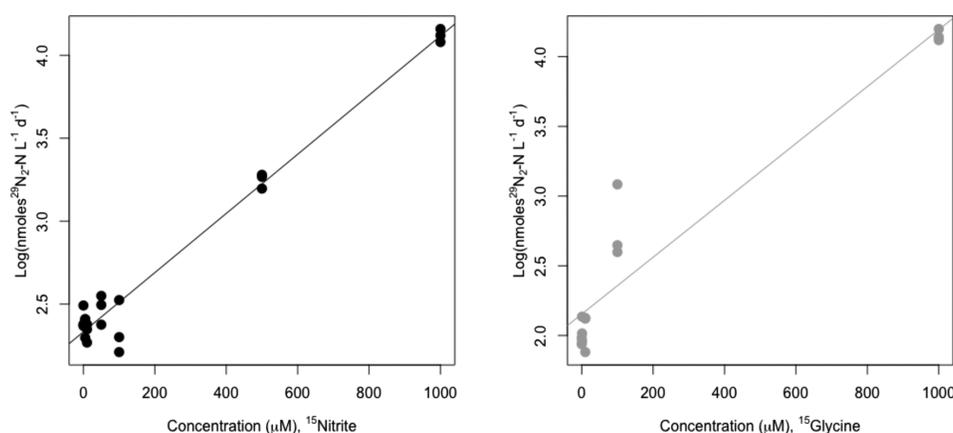

**3.3. Soil Mineral N, pH, TOC, and TN.** Extractable NO<sub>3</sub><sup>-</sup> concentrations in the sterile soils ranged from 0 to 3.06 μmoles g<sup>-1</sup> (Table 2). The soils with the lowest and highest NO<sub>3</sub><sup>-</sup> concentrations were NZ5 and US2, respectively. The extractable NH<sub>4</sub><sup>+</sup> concentrations ranged from 2.02 to 3.44 μmoles g<sup>-1</sup>. NZ1 had the lowest NH<sub>4</sub><sup>+</sup> concentration while NZ6 had the highest NH<sub>4</sub><sup>+</sup> concentration (Table 2). The pH in sterile soils ranged from 5.0 to 5.9 (Table 2). The lowest pH was observed in NZ5 and NZ6 samples (5.0), and the US2 had the highest pH (5.9). The soils (NZ5 and NZ6) with the highest <sup>29</sup>N<sub>2</sub> production had the lowest soil pH. The soils (US2) with the highest pH had the lowest <sup>29</sup>N<sub>2</sub> production. Table 2 lists soil TOC, TN, and carbon:nitrogen (C:N) ratio, where NZ6 and US3 stand out as substantively higher in TOC. The C:N ratio measured in soils ranged from 9 to 16 with the highest in US3, which also exhibited the highest N<sub>2</sub> production in the <sup>15</sup>NO<sub>2</sub><sup>-</sup> only treatment. C:N ratios for soils from NZ6 and NZ5 were higher and produced more <sup>29</sup>N<sub>2</sub> than soils from sites with a lower C:N ratio (NZ1 and US2).

**3.4. Abiotic Codenitrification in Buffer Solution under Varying N Conditions.** Higher production of <sup>29</sup>N<sub>2</sub> was observed as the concentration of <sup>15</sup>NO<sub>2</sub><sup>-</sup> increased in buffer solution experiments (Figure 2 and Table S1). <sup>29</sup>N<sub>2</sub>-N production was <10 nmoles N L<sup>-1</sup> Day<sup>-1</sup> when <sup>15</sup>NO<sub>2</sub><sup>-</sup> concentration was below 100 μM, whereas the highest rate was 30 nmoles N L<sup>-1</sup> day<sup>-1</sup> when <sup>15</sup>NO<sub>2</sub><sup>-</sup> concentration was 1000 μM. There was a statistically significant linear relationship between the concentration of <sup>15</sup>NO<sub>2</sub><sup>-</sup> and <sup>29</sup>N<sub>2</sub> production (*p*-value <0.001 and *R*<sup>2</sup> = 0.9734). Similarly, <sup>29</sup>N<sub>2</sub> production increased as the concentration of <sup>15</sup>N-Gly increased (Figure 2). The <sup>29</sup>N<sub>2</sub> production ranged from 3.84 nmoles N L<sup>-1</sup> Day<sup>-1</sup> to 31.82 nmoles N L<sup>-1</sup> Day<sup>-1</sup> with concentrations

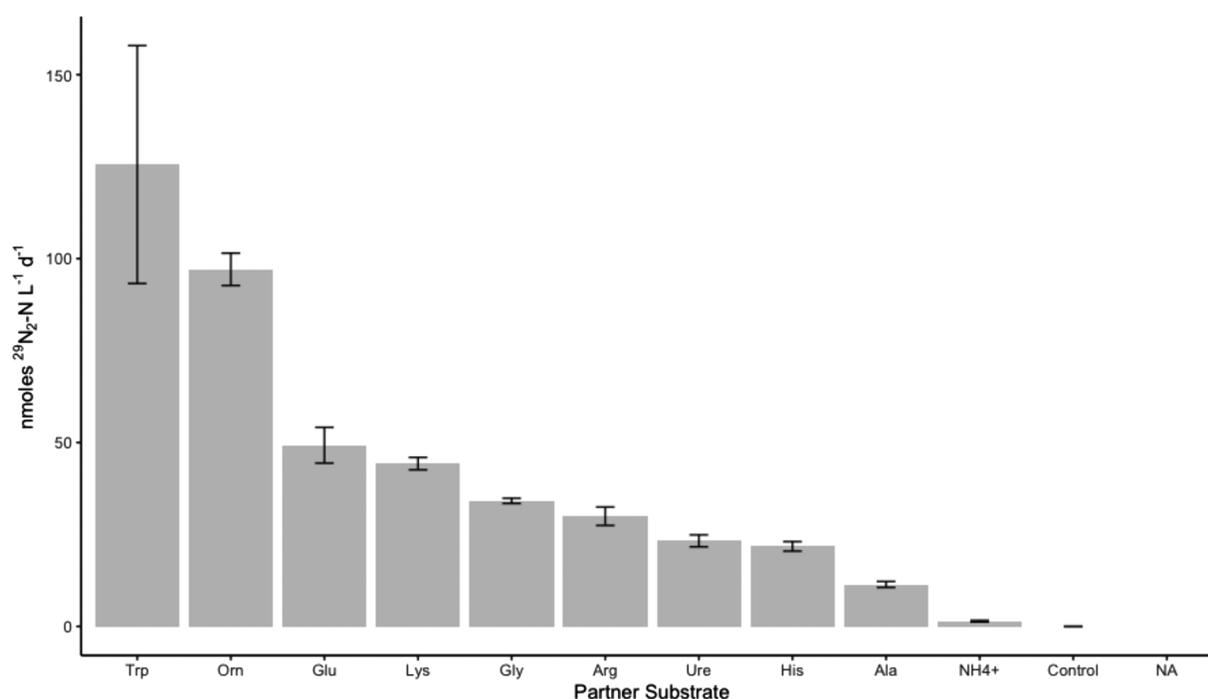

**Table 2. Soil Sample Characteristics Including the Sampling Site, Bulk Density, Percent Sand, Percent Silt, Percent Clay, Sterile Soil pH, Extractable NO<sub>3</sub><sup>-</sup> and NH<sub>4</sub><sup>+</sup> Concentrations, TOC, Total Organic Nitrogen, and C:N Ratio<sup>a</sup>**

<sup>a</sup>Extractable NO<sub>3</sub><sup>-</sup> concentrations were negligible or below detection limits.

**Figure 2.** Log-transformed concentration gradient data ( $\log(\text{nmoles } ^{29}\text{N}_2\text{-N L}^{-1} \text{d}^{-1})$ ) (points) and linear models (lines).  $\text{NO}_2^-$  concentration gradient linear model (black line),  $p$ -value  $<0.001$ , and  $R^2 = 0.97$ . Glycine concentration gradient linear model (gray line),  $p$ -value  $<0.001$ , and  $R^2 = 0.9$ .

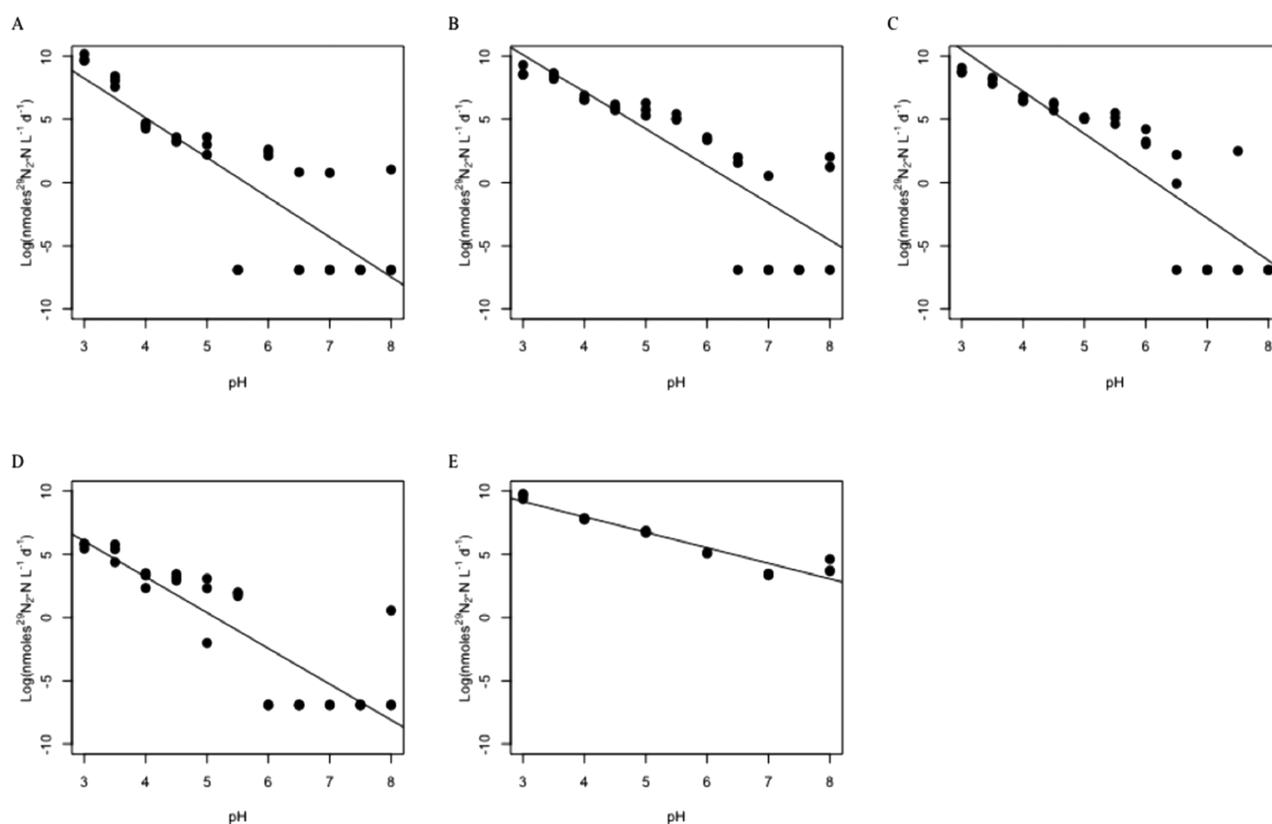

**Figure 3.** Abiotic  $^{29}\text{N}_2$  production rates for different partner-N substrates in buffer solution (pH 6). Two included controls are also shown: no substrate control with nitrite only (control) and a buffer control with a no nitrite and no partner substrate (NA). Each partner-N substrate was shown to be significantly different from the control sample ( $p$ -value  $<0.05$ ).

400 of 1  $\mu\text{M}$  and 1000  $\mu\text{M}$   $^{15}\text{N}$ -Gly, respectively. There was a  
401 statistically significant linear relationship between  $^{15}\text{N}$ -Gly and  
402  $^{29}\text{N}_2$  production ( $p$ -value  $<0.001$  and  $R^2 = 0.9041$ ).

403 Partner-N substrates ( $\text{NH}_4^+$ , Ure, Ala, Arg, Gly, Glu, His,  
404 Lys, Orn, or Trp) produced different amounts of  $^{29}\text{N}_2$  in the  
405 buffer solutions (pH 6) amended with  $^{15}\text{NO}_2^-$  (Figure 3). The  
406 highest  $^{29}\text{N}_2$  production was observed with Trp treatment;  
407  $125.57 \pm 32.34$  nmoles  $^{29}\text{N}_2 \text{L}^{-1} \text{Day}^{-1}$ . In comparison, the  
408 lowest  $\text{N}_2$  production was observed when  $\text{NH}_4^+$  was the  
409 partner substrate ammonium;  $1.42 \pm 0.21$  nmoles  $^{29}\text{N}_2 \text{L}^{-1}$   
410  $\text{Day}^{-1}$ . A one-way ANOVA indicated that the substrate had a  
411 significant effect on the  $^{29}\text{N}_2$  production ( $p$ -value  $<0.05$ ).  
412 Posthoc analysis indicated statistically significant differences  
413 ( $p$ -value  $<0.05$ ) between each partner substrate condition  
414 (substrate +  $^{15}\text{NO}_2^-$ ) and the  $^{15}\text{NO}_2^-$  only control.

### 3.5. Abiotic Codenitrification in Buffer Solution under Different pH and N Substrate Conditions.

415 The effects of different pH values and N substrates on abiotic  
416 codenitrification were tested with six different pH values (3, 4,  
417 5, 6, 7, and 8) and five N substrates ( $\text{NH}_4^+$ , Ure, Gly, Glu, and  
418 Orn). Regardless of the partner-N substrate,  $^{29}\text{N}_2$  production  
419 decreased as pH increased (Figure 4, Table S2). The Orn  
420 treatment produced the highest amount of  $^{29}\text{N}_2$ ,  $19,267.90 \pm$   
421  $5898.65$  nmoles  $\text{N L}^{-1} \text{Day}^{-1}$  at pH 3, but the  $^{29}\text{N}_2$  production  
422 rate declined markedly to  $30.00 \pm 17.32$  nmoles  $\text{N L}^{-1}$   
423 at pH 8. Ure produced the second highest amount of  $^{29}\text{N}_2$ ,  
424  $15,241.89 \pm 2953.69$  nmoles  $\text{N L}^{-1} \text{Day}^{-1}$  at pH 3 and  $90.97$   
425  $\pm 9.24$  nmoles  $\text{N L}^{-1} \text{Day}^{-1}$  at pH 4 and also had a decline to  
426  $0.94 \pm 0.81$  nmoles  $\text{N L}^{-1} \text{Day}^{-1}$  at pH 8. The  $^{29}\text{N}_2$  production  
427 was lowest in  $\text{NH}_4^+$  treatment, which exhibited a rate of  $18.22$   
428

**Figure 4.** Abiotic  $^{29}\text{N}_2$  production rates from different partner-N substrates along the pH gradient. Log of nmoles  $^{29}\text{N}_2\text{-N L}^{-1} \text{d}^{-1}$  along pH gradient data (observed data = points) and fitted models ( $^{29}\text{N}_2\text{-N} - m \times \text{pH} + b$ ) (linear model = line). (A) Urea pH gradient test (Urea +  $^{15}\text{NO}_2^-$ ):  $R^2 = 0.67$  and  $p\text{-value} = 3.272 \times 10^{-09}$ . (B) Glutamine pH gradient test (Glu +  $^{15}\text{NO}_2^-$ ):  $R^2 = 0.7$  and  $p\text{-value} = 6.429 \times 10^{-10}$ . (C) Glycine pH gradient test (Gly +  $^{15}\text{NO}_2^-$ ):  $R^2 = 0.79$  and  $p\text{-value} = 2.094 \times 10^{-12}$ . (D) Ornithine pH gradient test (Orn +  $^{15}\text{NO}_2^-$ ):  $R^2 = 0.92$  and  $p\text{-value} = 3.059 \times 10^{-10}$ .

430  $\pm 2.83$  nmoles  $\text{N L}^{-1} \text{Day}^{-1}$  at pH 4 and  $0.54 \pm 0.94$  nmoles  $\text{N}$   
 431  $\text{L}^{-1} \text{Day}^{-1}$  at pH 8. Although the magnitude of  $^{29}\text{N}_2$   
 432 production at each pH varied with the partner-N substrates,  
 433 the negative relationship between  $^{29}\text{N}_2$  production and pH was  
 434 consistent. There was a significant linear relationship between  
 435 pH and the natural log of  $^{29}\text{N}_2$  production rates for each  
 436 substrate tested (all  $p\text{-values} < 0.05$ , see Figure 4 and Table S2  
 437 for  $R^2$  values). Orn had the strongest linear relationship  
 438 between  $^{29}\text{N}_2$  production rates and pH ( $R^2 = 0.858$ ), whereas  
 439 ammonium had the weakest linear relationship ( $R^2 = 0.401$ ).

## 4. DISCUSSION

440 **4.1. Abiotic and Biotic  $\text{N}_2$  Production in Soils.** The net  
 441 rate of abiotic codenitrification in the environment depends  
 442 upon competition for  $\text{NO}_2^-$  between biotic and abiotic  
 443 processes. Soils are complex matrices with the capability of  
 444 producing  $\text{N}_2$  through abiotic codenitrification, codenitrifica-  
 445 tion, anammox, and denitrification. Anammox and codeni-  
 446 trification are biotic pathways that produce hybrid  $\text{N}_2$ , the  
 447 same product resulting from abiotic codenitrification. Here, we  
 448 report that abiotic  $\text{N}_2$  production contributed 0.8 to 8.2% to  
 449 the total  $\text{N}_2$  production in the acidic grassland soils. This is  
 450 within the range reported by Lim et al. (2018), where abiotic  
 451  $\text{NO}_2^-$  decomposition converted a significant fraction (10–  
 452 20%) of  $\text{NO}_2\text{-N}$  to nitroso-compounds. The importance of  
 453 organic matter in nitrosation reactions was detailed by  
 454 Williams<sup>32</sup> and is also noted here in this study. In our results,  
 455 the highest relative contribution of abiotic to biotic  $\text{N}_2$

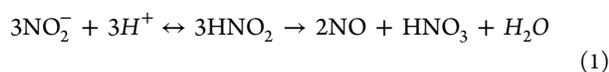

production was found in the soil with the highest C:N ratio 456  
 (NZ6). Higher C:N ratios are indicative of a less labile soil C 457  
 pool compared to soils with lower C:N ratios.<sup>33</sup> Our data 458  
 suggest that rates of abiotic codenitrification could be 459  
 influenced by larger pools of C relative to N, particularly if 460  
 the reaction introducing the  $\text{NO}^+$  ion to partner-N C atoms 461  
 increases when fewer N atoms are available. 462

**4.2. Abiotic  $\text{N}_2$  and  $\text{N}_2\text{O}$  Production in Soils.** Although 463  
 this study was focused on the  $\text{N}_2$  production by abiotic 464  
 codenitrification, it should be noted that  $\text{N}_2\text{O}$  can be produced 465  
 by abiotic processes such as chemodenitrification and nitro- 466  
 sation.<sup>7,24,34,35</sup> When abiotic  $\text{N}_2$  and  $\text{N}_2\text{O}$  production was 467  
 compared in this study, we observed that  $\text{N}_2\text{O}$  production was 468  
 a small fraction of the  $\text{N}_2$  produced in all samples. Our results 469  
 indicate that the major pathway of abiotic  $\text{NO}_2^-$  reduction is 470  
 abiotic codenitrification to  $\text{N}_2$ . Nitrosation reactions require 471  
 hydroxylamine or oxime compounds with an oxidation state of 472  
 -I to produce  $\text{N}_2\text{O}$ .<sup>7</sup> The low production of  $\text{N}_2\text{O}$  in acidic soils 473  
 could be explained by low availability of the compounds that 474  
 react with  $\text{NO}_2^-$  to produce  $\text{N}_2\text{O}$ . However, this study clearly 475  
 demonstrates that abiotic codenitrification producing hybrid 476  
 $\text{N}_2$  is the major pathway of abiotic N removal in acidic soils 477  
 and that abiotic  $\text{N}_2$  production can be enhanced by the 478  
 addition of amino acids commonly found in soils.<sup>30</sup> 479

**4.3. Controlling Factors of Abiotic Codenitrification** 480  
**in Soils.** The results of the incubation experiments with five 481  
 different sterile soils revealed potential factors controlling 482  
 abiotic codenitrification. Abiotic codenitrification was greater 483

484 for sterile soils collected at the US3, NZ5, and NZ6 sites,  
485 where pH ranged between 5.0 and 5.3. Soil pH for the two  
486 soils with the lowest N<sub>2</sub> production (NZ1 and US2) was 5.6  
487 and 5.9, respectively. The importance of pH and NO<sub>2</sub><sup>-</sup>  
488 concentration has been corroborated by numerous studies  
489 where both NO<sub>2</sub><sup>-</sup> and an organic-N nitrosation partner were  
490 available in soils.<sup>12,27,36</sup> Recently, a sterile peat reportedly  
491 produced N<sub>2</sub> at pH < 5, but not at pH > 7.<sup>12</sup> Results of a NO<sub>2</sub><sup>-</sup>  
492 tracer experiment reported that abiotic production of N<sub>2</sub> and  
493 N<sub>2</sub>O (the nitrosation agent NO derived from the decom-  
494 position of HNO<sub>2</sub>) was elevated in acidic soils.<sup>13</sup> While pH  
495 was not manipulated in the soil experiments, more N<sub>2</sub> was  
496 produced from acidic soils, and the preponderance of the data  
497 in the literature points to pH as a controlling factor for abiotic  
498 codenitrification.

499 The soils amended with Glu and <sup>15</sup>NO<sub>2</sub><sup>-</sup> had higher rates of  
500 abiotic codenitrification than the ones with <sup>15</sup>NO<sub>2</sub><sup>-</sup> only  
501 (Figure 1). This finding is consistent with the previous studies  
502 reporting the importance of organic matter in the abiotic  
503 immobilization of NO<sub>2</sub><sup>-</sup> in sediment<sup>14</sup> and soil<sup>16</sup> and the  
504 concomitant production of N<sub>2</sub> gas.<sup>6</sup> While all soils responded  
505 positively to Glu addition, this was most evident for NZ6  
506 volcanic soil, which doubled N<sub>2</sub> production by abiotic  
507 codenitrification. NZ6 volcanic soil is an allophane soil,  
508 which is characteristically higher in TOC and specific surface  
509 area, as compared to nonallophanes.<sup>37</sup> The specific surface area  
510 of allophanes is reportedly 700 m<sup>2</sup> g<sup>-1</sup>, which is similar to the  
511 specific surface area of organic matter,<sup>39</sup> ranging from 580 to  
512 800 m<sup>2</sup> g<sup>-1</sup>. The allophane then provides more organic matter  
513 required for the nitrosation reaction and more surface area.  
514 Both organic matter and mineral particle surfaces are sites  
515 where the self-decomposition of HNO<sub>2</sub> to NO can occur.<sup>40</sup>  
516 NO<sub>2</sub><sup>-</sup> is the most efficient species of DIN in terms of the  
517 reaction with soil organic matter to form organic N and N<sub>2</sub>  
518 precisely because of the NO spontaneously produced at low  
519 pH<sup>16</sup>. Chemical formation of NO occurs when NO<sub>2</sub><sup>-</sup> is  
520 converted to nitrous acid at low pH, which then decomposes  
521 to NO and HNO<sub>3</sub> as described below:<sup>9</sup>

523 It is important to note in this discussion that a full-throated  
524 investigation of how  $\gamma$  irradiation affected each of these  
525 disparate soils was outside the scope of the project, but worthy  
526 of future consideration, so sterile soil measurements may not  
527 directly align with live soil measurements for abiotic  
528 codenitrification. NO<sub>2</sub><sup>-</sup> in a sterile acidic peat (pH < 5) with  
529 45% TOC was more readily used by microbes for  
530 denitrification, although abiotic production of N<sub>2</sub> (2 to 14  
531 nmoles g<sup>-1</sup> day<sup>-1</sup>) was observed.<sup>12</sup> Soils reported here are for  
532 grasslands, where TOC < 5% resulted in N<sub>2</sub> production of 1  
533 nmole N g<sup>-1</sup> day<sup>-1</sup> at pH > 5. At higher levels of NO<sub>2</sub><sup>-</sup>  
534 addition, a sterile NZ soil produced over 700 nmoles N g<sup>-1</sup>  
535 over the initial 24 h of an incubation time series.<sup>21</sup> These NZ  
536 soils were similar to NZ1 Stony with respect to pH and organic  
537 matter, so higher NO<sub>2</sub><sup>-</sup> addition likely explains the contrast in  
538 abiotic hybrid N<sub>2</sub> production rates.

539 **4.4. Effect of N Concentration on Abiotic Codeni-**  
540 **trification.** Abiotic hybrid <sup>29</sup>N<sub>2</sub> production increased linearly  
541 with <sup>15</sup>NO<sub>2</sub><sup>-</sup> concentration. Similarly, abiotic hybrid <sup>29</sup>N<sub>2</sub>  
542 production increased linearly with <sup>15</sup>N-Gly concentration.  
543 These results confirm that rates of abiotic codenitrification are  
544 dependent on both NO<sub>2</sub><sup>-</sup> and partner-N concentrations. Van

Cleemput et al. (1995) also reported abiotic gaseous N  
545 production at high NO<sub>2</sub><sup>-</sup> concentrations, but they did not  
546 include low concentrations that may be observed in the  
547 environment.<sup>19</sup> Abiotic N<sub>2</sub> production above 10 nmoles L<sup>-1</sup>  
548 day<sup>-1</sup> was not observed below a concentration of 100  $\mu$ M for  
549 either substrate (<sup>15</sup>NO<sub>2</sub><sup>-</sup> or <sup>15</sup>N-Gly). This could indicate  
550 either a substrate concentration threshold for N<sub>2</sub> formation by  
551 abiotic codenitrification or a detection limit for measuring  
552 small changes in <sup>29</sup>N<sub>2</sub> production at lower concentrations. 553

**4.5. Effects of Partner-N Substrates on Abiotic**  
554 **Codenitrification.** We found specific N substrates commonly  
555 found in soils<sup>30</sup> varied in their effects on abiotic hybrid N<sub>2</sub>  
556 production in buffer solution experiments. Trp- and Orn-  
557 treated samples exhibited the highest N<sub>2</sub> production, whereas  
558 the lowest N<sub>2</sub> production was observed in samples with NH<sub>4</sub><sup>+</sup>.  
559 Among various characteristics of each N substrate (Table 3), 560 13

**Table 3. Characteristics of Amino Acids Used as Partner-N Substrates in Buffer Solution Experiments Including Polarity, Acidic/Basic, Number of Amine Groups, Molecular Weight, and C:N Ratio**

amino acid	polarity	acidic/basic	#of amine groups	molecular weight g/mol	C:N
ammonium	polar	neutral	1	53.49	
urea	nonpolar	neutral	2	60.06	1:2
alanine	nonpolar	neutral	1	89.09	3:1
arginine	polar	basic	3	174.20	4:4
glycine	nonpolar	neutral	1	75.07	2:1
glutamine	nonpolar	neutral	2	146.14	5:2
histidine	polar	basic	3	155.15	5:3
lysine	polar	basic	2	146.20	6:2
ornithine	polar	moderately acidic	2	168.6	5:2
tryptophan	slightly polar	neutral	2	204.23	11:2

the C:N ratio had a significant linear relationship with N<sub>2</sub>  
561 production ( $p$ -value < 0.05 and  $R^2 = 0.6411$ ) as well as with  
562 molecular weight ( $p$ -value < 0.05 and  $R^2 = 0.5335$ ).  
563 Interestingly, when comparing the C:N ratio of each soil  
564 sample with N<sub>2</sub> production, the same pattern was observed in  
565 the soil incubation experiments. The C:N ratio may be an  
566 important factor for abiotic codenitrification occurring in  
567 recalcitrant organic matter or humic substances, which have  
568 high C:N ratios and may not be widely used by biotic  
569 processes.<sup>30</sup> 570

**4.6. Effects of pH and N Partner Substrates on**  
571 **Abiotic Codenitrification.** Five N substrates, including  
572 NH<sub>4</sub><sup>+</sup>, Ure, Gly, Glu, and Orn, were tested along a pH  
573 gradient (3–8) for N<sub>2</sub> production with <sup>15</sup>NO<sub>2</sub><sup>-</sup>. All partner-N  
574 substrates tested in solutions with <sup>15</sup>NO<sub>2</sub><sup>-</sup> exhibited increased  
575 N<sub>2</sub> production at low pH. A significant negative linear  
576 relationship between pH and <sup>29</sup>N<sub>2</sub> production was observed  
577 for each of the different substrates. This aligns with previous  
578 studies reporting increased abiotic hybrid N<sub>2</sub> production at low  
579 pH.<sup>12</sup> This also agrees with the soil incubations in which  
580 higher N<sub>2</sub> production from soils with lower pH was observed.  
581 These buffer solution experiments isolated pH from other,  
582 potentially confounding factors commonly present in environ-  
583 mental samples. 584

The results of the pH gradient testing indicate that there  
585 may be substantial N removal capacity by abiotic codeni-  
586

587 trification in low-pH environments. High reactivity of Ure to  
588 abiotic codenitrification at low pH values is of particular  
589 significance as Ure is commonly used as an agricultural  
590 fertilizer. According to the International Fertilizer Association,  
591 Ure accounts for >57% of the global fertilizer demand.<sup>41</sup> The  
592 widespread use of Ure and its high reactivity to abiotic  
593 codenitrification could lead to significant N losses by abiotic  
594 codenitrification, especially in acidic soils. Acidic environments  
595 may include but are not limited to acidic soils, cave systems,  
596 and acid mine drainage sites. Abiotic codenitrification may be  
597 an important N removal process under acidic conditions,  
598 which can be unfavorable for microbial N removal  
599 processes.<sup>42,43</sup> Glass and Silverstein showed that in batch  
600 reactors, denitrification was inhibited at  $\text{pH} < 7.0$ .<sup>42</sup> Waring  
601 and Gilliam confirmed that denitrification may be inhibited at  
602 low pH,<sup>43</sup> but the threshold of pH tolerance was unclear.  $\text{N}_2$   
603 production by anammox bacteria also decreases at low pH.<sup>44</sup>  
604 The potential inhibition of microbial N removal processes at  
605 low pH suggests that abiotic codenitrification could dominate  
606 over biotic codenitrification in low-pH environments. An ideal  
607 location where abiotic codenitrification may be a major  
608 pathway of N removal could be urine patches in agricultural  
609 soils; these areas are typically high in organic N compounds  
610 such as urea but also have high  $\text{NO}_2^-$  concentrations.<sup>35,45,46</sup>

## 5. CONCLUSIONS

611 Abiotic codenitrification is an important N removal process in  
612 acidic soils with low labile organic C to support biotic  
613 processes. We found that abiotic  $\text{N}_2$  production is much  
614 greater than abiotic  $\text{N}_2\text{O}$  production and contributes up to  
615 8.2% of total  $\text{N}_2$  production in the acidic soils examined.  
616 Abiotic codenitrification is enhanced by the addition of organic  
617 N such as Glu. The magnitude of the effect of Glu addition,  
618 however, varies with soil properties, such as pH. Here, we show  
619 that substrate concentration, pH, and partner-N compounds  
620 are all important factors determining the magnitude of  $\text{N}_2$   
621 produced by abiotic codenitrification. Our results indicate that  
622  $\text{N}_2$  production by abiotic codenitrification increases with  
623 increasing substrate concentration and decreasing pH and  
624 shows differential activity with various compounds favoring  
625 those with a high molecular weight and C:N ratio. In situ,  
626 abiotic processes may persist where microbial pathways are  
627 inhibited or are disfavored, for example, in the environments  
628 enriched with recalcitrant organic matter and/or with low pH.  
629 This gives insight into the potential hotspots of abiotic  
630 codenitrification and the required conditions for this reaction  
631 such as in agricultural soils and ruminant urine patches. The  
632 contribution of abiotic codenitrification to N removal in the  
633 environment remains unconstrained because of difficulties  
634 discriminating from abiotic codenitrification from biotic  
635 processes. Further research is needed to fully understand the  
636 implications of abiotic codenitrification to the greater N cycle  
637 and budgets.
